The abundance of  $^{180}\text{W}$  in iron meteorites is variable and differs from the terrestrial value. Previously, we have shown that this variability can largely be explained by in situ radiogenic production of  $^{180}\text{W}$  by  $\alpha$ -decay of  $^{184}\text{Os}$  ( $t_{1/2} \sim 1.1 \times 10^{13}$  year) [1]. Consequently, geological processes that fractionate Os from W may be recorded in the  $^{180}\text{W}$  inventories of planetary materials. Here, we elaborate on the possibility that the  $^{180}\text{W}$  inventory of the silicate Earth was affected by the mixing of chondritic material that was derived from a 'late veneer' into the mantle. Furthermore, we demonstrate that terrestrial silicates display a resolvable deficit in  $^{180}\text{W}$  relative to chondrites that is consistent with core formation  $\sim 4.5$  Ga ago followed by differentiation of the silicate mantle. Some technical issues related to improving measurement precisions of  $^{180}\text{W}$  are discussed. [1] Peters et al. (2013) *LPI* 1719, 2073
